Formal Specification of the Plutus Core Language

I. Plutus Core

Plutus Core is an untyped λ calculus design to run as a transaction validation scripting language on blockchain systems. It's designed to be simple and easy to reason about using mechanized proof assistants and automated theorem provers. The grammar of the language is given in Figure 1, using an s-expression format. As is standard in λ calculi, we have variables, λ abstractions, and application. In addition to this, there are also local let bindings, data constructors which have arguments, case terms which match on term, declared names, computational primitives (success, failure, and binding), primitive values, and built-in functions. Terms live within a top-level program which consists of some declarations.

As a few examples, consider the program in Figure 2, which defines the factorial and map functions. This program is not the most readable, which is to be expected from a representation intended for machine interpretation rather than human interpretation, but it does make explicit precisely what the roles are of the various parts.

II. Scope Correctness

We define for Plutus Core a scope correctness judgment, which explains when a program's use of scoped objects (variables and names) is valid. This judgment is defined inductively as shown in Figure 4, with auxiliary judgments in Figure 6.

Plutus Core's module system defines two kinds of declared names. Names declared using the `exp` and `expcon` keywords are exported declaration of terms and constructors, respectively, and are usable by any other module. Names declared using the `loc` and `loccon` keywords are local, and usable only in their declaring modules. This distinction between exported and local names permits a simple form of abstraction at the module level.

III. Execution and Reduction

The execution of a program in Plutus Core does not in itself result in any reduction. Instead, the declarations are bound to their appropriate names in a declaration environment δ, which we will represent by a list of items of the form $\mathrm{n} \mapsto M$. Then, designated names can be chosen to be reduced in this declaration environment generated. For instance, we might designate the name main to be the name who's definition we reduce, as is done in Haskell. The generation judgment for generating this is given by the relation $P \ggg \delta$, defined in Figure 7.

To give the computation rules for Plutus Core, we must define what the values are of the language, as given in Figure 8. Rather than using values directly, we wrap them in a return value form, because reduction steps can fail. These then let us define a parameterized binary relation $M \to^*_\delta R$ which means M reduces to R using declarations δ, in Figure 11. This uses a standard contextual dynamics to separate the local reductions, reduction contexts, and repeated reductions into separate judgments. We also define a step-indexed dynamics $M \to^n_\delta R$, which means that M reduces to R using δ in at most n steps. Step-indexed reduction is useful in settings where we want to limit the number of computational steps that

can occur.

One such setting for step-indexing is that of blockchain transactions, for which Plutus Core has been explicitly designed. In order to prevent transaction validation from looping indefinitely, or from simply taking an inordinate amount of time, which would be a serious security flaw in the blockchain systemn, we can use step indexing to put an upper bound on the number of computational steps that a program can have. In this setting, we would pick some upper bound max and then perform reductions of terms M by computing which R is such that $M \rightarrow^{max}_{h,bn,t,\delta} R$.

$$\boxed{\Delta \ ; \ \Gamma \ \vdash \ M \ term \ \mathrm{l}}$$

Term M in module l is well-formed with names in nominal context Δ and variables in variable context Γ

$$\frac{\Gamma \ \ni \ x}{\Delta \ ; \ \Gamma \ \vdash \ x \ term \ \mathrm{l}}$$

$$\frac{}{\Delta \ ; \ \Gamma \ \vdash \ \texttt{blocknum} \ term \ \mathrm{l}}$$

$$\frac{}{\Delta \ ; \ \Gamma \ \vdash \ \texttt{blocktime} \ term \ \mathrm{l}}$$

Fig. 4. Scope Correctness

Note that while case clauses can in principle be redundant, with the same constructor used in multiple clauses of the case expression, the definition of matching renders that redundancy irrelevant. The first clause with a matching constructor is the only one that is ever used.

In the setting of a blockchain oriented system, some blockchain-based properties are useful when writing scripts. The three that are supported by Plutus Core, in the form of the computational primitives `txhash`, `blocknum`, and `blocktime`, are the hash of the transaction that hosts the script being run, the block number of the block that hosts the transaction, and the block time of that block. We therefore require that when a program G is run in a transaction tx, in block bk, that the reduction parameters are $h = hash(tx)$, $bn = blockNumber(bk)$, and $t = blockTime(bk)$.

Because built-in reduction is implemented directly in terms of meta-language functionality, the specifications for them are subtly different than for other parts of this spec. In particular, we must explain what these meta-language implementations

$$\frac{}{\Delta\ ;\ \Gamma\ \vdash\ (\texttt{primInt}\ i)\ term\ 1}$$

$$\frac{}{\Delta\ ;\ \Gamma\ \vdash\ (\texttt{primFloat}\ f)\ term\ 1}$$

$$\frac{}{\Delta\ ;\ \Gamma\ \vdash\ (\texttt{primByteString}\ b)\ term\ 1}$$

$$\frac{\Delta\ ;\ \Gamma\ \vdash\ M_i\ term\ 1}{\Delta\ ;\ \Gamma\ \vdash\ (\texttt{builtin}\ \mathrm{n}\ \vec{M})\ term\ 1}$$

$$\frac{\Delta\ ;\ \Gamma\ \vdash\ M\ term\ 1}{\Delta\ ;\ \Gamma\ \vdash\ (\texttt{isFun}\ M)\ term\ 1}$$

$$\frac{\Delta\ ;\ \Gamma\ \vdash\ M\ term\ 1}{\Delta\ ;\ \Gamma\ \vdash\ (\texttt{isCon}\ M)\ term\ 1}$$

$$\frac{\Delta\ ;\ \Gamma\ \vdash\ M\ term\ 1}{\Delta\ ;\ \Gamma\ \vdash\ (\texttt{isConName}\ n\ M)\ term\ 1}$$

$$\frac{\Delta\ ;\ \Gamma\ \vdash\ M\ term\ 1}{\Delta\ ;\ \Gamma\ \vdash\ (\texttt{isInt}\ M)\ term\ 1}$$

$$\frac{\Delta\ ;\ \Gamma\ \vdash\ M\ term\ 1}{\Delta\ ;\ \Gamma\ \vdash\ (\texttt{isFloat}\ M)\ term\ 1}$$

$$\frac{\Delta\ ;\ \Gamma\ \vdash\ M\ term\ 1}{\Delta\ ;\ \Gamma\ \vdash\ (\texttt{isByteString}\ M)\ term\ 1}$$

Fig. 5. Scope Correctness (cont.)

are that constitute the implicit spec. Primitive numeric ints are implemented as Haskell Ints, primitive floats as $Float$, and primitive bytestrings as $ByteString$. For numeric built-ins, the operations are interpreted as the corresponding Haskell operations. So for example, $addInt$ is interpreted as $(+) :: Int- > Int- > Int$. The function names designated in the relevant equations are the same as the Haskell implementations where applicable. Some minor differences exist in some places, however. $drop(x, y)$ in the spec corresponds to the Haskell code $drop(fromIntegral x)y$, and similarly for $take$, simply because of how these functions are implemented for $ByteString$. The cryptographic functions $sha2\_256$ and $sha3\_256$ are also different, this time more so. They are implemented in terms of hashing into the $SHA256$ and $SHA3256$ digest types using the $Crypto.Hash$ and $Crypto.Sign.Ed25519$ modules. More indirectly, the specification for these are the cryptographic standards for SHA2 256 and SHA3 256.

A final note on built-in reduction is that some built-ins return constructed data using qualified names in the $Prelude$ module. This specification assumes that an implementation will have such a module defined, that it declares exported constructors names $True$ and $False$, and that it will always incorporated it as part of any use of Plutus Core usage so that the results of these built-ins can be used by programs in case expressions.

Note that the success and failure terms are not effectful. That is to say, `failure` does not throw an exception of any sort. They are merely primitive values that represent computational success and failure. They are analogous to Haskell Maybe values, except that they cannot be inspected, and all computational control is done via the $bind$ construct.

IV. Basic Validation Program Structure

The basic way that validation is done in Plutus Core is slightly different than in Bitcoin Script. Whereas in Bitcoin Script, a validation is successful if the validating script successfully executes and leads $true$ on the top of the stack, in Plutus Core, we have special data constructs for validation. In particular, the (`success` V) and `failure`. Any program which validates a transaction must declare a function (`decname` (`qual` Validator validator)), while the corresponding program supplied by the redeemer must declare (`decname` (`qual` Redeemer redeemer)). The declarations of both are combined into a single set of declarations, and these two declared terms are then composed with a bind. The overall validation, therefore, involves reducing the term

(`bind`
  (`decname` (`qual` Redeemer redeemer))
  x
  (`app` (`decname` (`qual` Validator validator)) x))

If this reduces to (`ok` (`success` V)) for some V, then the transaction is valid, analogous to Bitcoin Script successfully executing and leaving $true$ on the top of stack. On the other hand, if it reduces to (`ok failure`) or to `err`, then the transaction is invalid, analogous to Bitcoin Script either leaving $false$ on the top of stack, or failing to execute. The value returned in the success case is irrelevant to validation but may be used for other purposes.

$\boxed{\Delta \ permits \ qn \ in \ l}$

Nominal context Δ permits the use of qualified name qn in module l

$$\frac{\Delta \ \ni \ \mathrm{l}' \ exp \ \mathrm{n}}{\Delta \ permits \ (\texttt{qual} \ \mathrm{l}' \ \mathrm{n}) \ in \ l}$$
